RESUMEN

En este artículo usamos las observaciones presentadas en Rozas (2007) de la galaxia NGC 5055 en las líneas $H\alpha$ y $H\beta$, junto con observaciones CCD con filtros estrechos en las líneas [OII], [OIII], [SII] y S[III] para calcular las anchuras equivalentes, excitación, grados de ionización, parámetros de ionización y metalicidades de las regiones catalogadas en Rozas (2007).

ABSTRACT

In this paper, using CCD observations of the galaxy NGC 5055 in the emission lines of $H\alpha$ and $H\beta$ (Rozas 2007), together with CCD observations in the narrow-band filters of [OII], [OIII], [SII], and S[III] lines we have calculated the equivalent widths, excitations, ionization hardness, ionization parameters and metallicities for the regions catalogued in Rozas (2007).

Key Words: galaxies: individual (NGC 505) — galaxies: kinematics and dynamics
— galaxies: spiral

1. INTRODUCTION

We obtained images of the spiral galaxy NGC 5055 during the nights of 2005 June 14th–18th, with the 0.84 m telescope of the Observatorio Astronómico Nacional in the Sierra San Pedro Mártir. We obtained the images using narrow band filters for the wavelengths $H\alpha$, $H\beta$, [OII] $\lambda\lambda$ 3726, 3729, [OIII] λ 5007, [SII] $\lambda\lambda$ 6717, 6731 and [SIII] λ 9069 and their respective continuum filters. In Rozas (2007, hereafter Paper I) we catalogued 372 HII regions and calculated their statistical properties: the luminosity function and the geometrical distributions. In this second paper we present the physical properties of the HII regions catalogued: their equivalent widths, excitations, ionization hardness, ionization parameters and metallicities.

In Figure 1 of Paper I we show a grey scale representation of the $H\alpha$ image of NGC 5055. The spiral arms show up as a grainy background, which brightens slowly from the periphery to the nuclear region, which is still grainy. Star forming regions can be traced along the spiral arms. NGC 5055 has been studied previously in ^{12}CO (J=1-0) by Tosaki et al. (2002) and in HI by Battaglia et al. (2006). These authors note the regularity and symmetry of the galaxy, but a mild lopsidedness is noticeable, both

in the distribution and the kinematics of the gas. The tilted ring analysis of the velocity field suggests a range of values for the kinematical center and different systemic velocities for the inner and the outer parts of the system. This implies a remarkable result: the kinematical and geometrical asymmetries disappear, both at the same time. These results point to two different dynamical regimes: an inner region dominated by the stellar disk and an outer region dominated by a dark matter halo, offset with respect to the disk.

In this paper we aim to complete these earlier studies by observing a significant number of HII regions in several emission lines in order to be able to extract conclusions about the star formation trends that occur in spiral galaxies.

2. OBSERVATIONS AND DATA REDUCTION

The observations and data reduction procedures for the $H\alpha$ and $H\beta$ images are summarized in § 2 of Paper I. The observations of NGC 5055 in the other lines were made during the same nights of June 14th–18th 2005 with the 0.84 m telescope of the Observatorio Astronómico Nacional in the Sierra San Pedro Mártir. The detector was a Site 1 CCD. The projected pixel size was $0.39''/\text{pix}$. The observing

TABLE 1
FILTERS USED AND EXPOSURE TIMES

OII	3725	5×1500 s
OII cont	3500	1800 s
OIII	5012	5×1500 s
OIII cont	5470	1800 s
SII	6737	6×1800 s
SII cont	7157	3×1500 s
SIII	9150	8×1500 s
SIII cont	8510	4×1500 s

conditions were very good with $1''$ seeing and a photometric sky.

Table 1 shows the filters used and the exposure times. The first column lists the name of the filter, the second column contains the central wavelength for each filter in angstroms, and the last column indicates the exposure time employed for each filter. Standard reduction routines were used, closely following the procedure of previous studies. A bias level was first subtracted, and the images were then corrected using appropriate dawn sky flatfields. Next, a value for the sky background was obtained by measuring the background and the associated noise levels in portions of the image where there was no emission from the galaxy. In order to align the two images (line and continuum images), positions of several foreground stars were determined based upon Gaussian fits, and the off-band images were displaced to coincide with the on-band images. The accuracy of the superpositions was better than 0.3 pixels in all cases.

Once the aligned images were cleaned of cosmic rays and of the occasional bad pixels, the continuum images were subtracted from the line image, giving net fluxes. To subtract the continuum, all the continuum images were multiplied by factors that turned out to be close to unity. These factors were determined assuming that the inter-arm emission was null after the subtraction. This was preferred to the field star method, because these stars may present different spectral energy distributions from that of the stellar population of the galaxy, and also they may present strong absorption lines, so the correction factors will be underestimated or overestimated. Moreover, using this method we are able to correct every line for diffuse background emission. Figures 1–4 present the resulting emission line images for NGC 5055 in [OII], [OIII], [SII] and [SIII].

Fig. 1. Grey scale representation of the [OII] continuum-subtracted image of NGC 5055.

Fig. 2. NGC 5055 [OIII] continuum subtracted.

In Paper I, we explained the procedure to carry out a correction for the effect of galactic and extragalactic extinction using the ratio of the $H\alpha$ and $H\beta$ fluxes.

3. RESULTS

Table 2 summarizes the flux for several emission lines for NGC 5055. Columns 1, 6 and 11 list the

Fig. 3. NGC 5055 [SII] continuum subtracted.

Fig. 4. NGC 5055 [SIII] continuum subtracted.

identification number of the region. Columns 2–5, 7–10 and 12–15 list the [OII], [OIII], [SII] and [SIII] ratios with respect to $H\beta$. All the quantities are relative to $H\beta=100$ and are corrected for extinction. We have assumed the theoretical relations: $I([\text{OIII}]\lambda\lambda 4959, 5007) = 1.34 I([\text{OIII}]\lambda 5007)$ and $I([\text{SIII}]\lambda\lambda 9069, 9532) = 3.43 I([\text{SIII}]\lambda 9069)$.

In Table 3 we summarize several quantities derived for the line ratios. Columns 1, 4 and 9 list the

region identification number, Columns 2, 5 and 10 the R_{23} parameter defined by Pagel et al. (1979):

$$R_{23} = \frac{I([\text{OII}]\lambda 3727) + I([\text{OIII}]\lambda\lambda 4959, 5007)}{I(H\beta)} \quad (1)$$

This parameter is an empirical oxygen abundance indicator when the temperature-sensitive lines, such as $[\text{OIII}]\lambda 4363$, are unavailable. Columns 3, 6 and 11 list the oxygen abundance derived from the calibration of Zaritsky, Kennicutt, & Huchra (1994):

$$12 + \log(O/H) = 9.265 - 0.33x - 0.202x^2 - 0.207x^3 - 0.333x^4, \quad (2)$$

where $x = \log R_{23}$.

Columns 4, 7 and 12 list the η parameter defined as:

$$\eta = \frac{[\text{OII}]\lambda\lambda 3726, 3729 / [\text{OIII}]\lambda\lambda 4959, 5007}{[\text{SII}]\lambda\lambda 6717, 6731 / [\text{SIII}]\lambda\lambda 9069, 9532} \quad (3)$$

This parameter scales roughly with the actual ionic ratios of oxygen and sulfur and, hence, provides an indicator of the hardness of the ionizing spectrum. This parameter does not depend strongly upon the electron temperature or density, or upon the reddening. It is related to the γ parameter (Vílchez & Pagel 1988),

$$\gamma = \frac{O^+/O^{++}}{S^+/S^{++}} \quad (4)$$

via the relation:

$$\log \gamma = \log \eta + \frac{0.14}{t} + 0.16, \quad (5)$$

where $t = T_e/10^4$, T_e being the electron temperature. Furthermore, it assumes the low density limit for ionic emissivities and ignores any temperature fluctuations.

3.1. Extinction

To obtain the values for the extinction, we employed the relation given in Paper I, equation (1):

$$A_V = 2.5 \ln \frac{(FH\alpha/FH\beta)_{\text{observed}}}{2.86} \quad (6)$$

Figure 5 shows a histogram representing the number of regions with different extinction values. The mean value obtained for the extinction is $A_V = 0.81$ mag. There are many regions with values for the extinction close to 1.0 mag and distributed in a somewhat Gaussian form.

Fig. 5. Histogram for extinction in NGC 5055.

Fig. 6. Histogram for log of $H\alpha$ equivalent width in NGC 5055.

3.2. Equivalent widths

The $H\alpha$ equivalent width provides a measure of the ratio of ionizing photons from massive stars and continuum photons from the embedded stars and gas. For this reason, this parameter is sensitive to variations of the initial mass function (IMF), the evolutionary stage of ionizing stars and their metallicity

(Leitherer et al. 1999; Kennicutt, Keel, & Blha 1989; Martin & Friedli 1999; Bresolin & Kennicutt 1997). Generally, the $EW(H\alpha)$ in disc galaxies goes from 100 Å to 1500 Å, with a mean value of 400 Å.

In Figure 6 we show the histogram for the logarithm of the $H\alpha$ equivalent width for HII regions in NGC 5055. The mean value for this galaxy is

Fig. 7. H α equivalent width as a function of galactocentric radius for NGC 5055.

$\log(\text{EW}[\text{H}\alpha])=3.15$, which is equivalent to an age of between 1.6 and 4 Myr, depending upon the IMF selected (using Leitherer et al. 1999 models).

Figure 7 shows the H α equivalent width for the HII regions as a function of galactocentric radius for NGC 5055. The general trend is an almost constant

value for the equivalent width with the radius, which indicates that the diffuse emission from the disc was successfully removed.

3.3. Excitation

The HII regions can be classified as “high excitation” or “low excitation” in terms of large or small values of the ratio $[\text{OIII}]/\text{H}\beta = I(\lambda\lambda 5007, 4959)/I(\lambda 4861)$ (Aller 1942; Searle 1971). Empirically, strong [OIII] lines are related to low oxygen abundances, high gas temperatures and a large values of $X(\text{O}^{+2})$, where X is a nebular average (Searle 1971; Smith 1975; Shields 1990). Figure 8 shows the excitation as a function of galactocentric radius for NGC 5055. The figure indicates that the excitation increases with radius. This increase in the excitation can be explained as an effect of the metallicity gradient that will be discussed later.

Figure 9 shows the correlation between $\log([\text{OII}]/\text{H}\beta)$ and the log of the excitation for each HII region of the galaxy. As we can see, the HII regions of NGC 5055 cover all the excitation range, with regions of low excitation in the inner parts of the galaxy and high excitation in the outer parts.

Fig. 8. Excitation as a function of galactocentric radius for NGC 5055.

Fig. 9. Correlation between $\log([OII]/H\beta)$ and the logarithm of excitation.

According to McCall, Rybski, & Shields (1985), the clear correlation between $\log([OII]/H\beta)$ and $\log([OIII]/H\beta)$ and the low dispersion of the data implies that the majority of the HII regions are ionization bounded.

3.4. Metallicity

As was indicated above, we obtained the metallicity using the calibration given by Zaritsky et al. (1994), based upon the R_{23} parameter. This estimator is precise to about 0.2 dex (Pagel, Edmunds, & Smith 1980), and it is double-valued in the range $0.9 < \log R_{23} < 1$, which introduces more uncertainties in the metallicity determination for HII regions with these values of $\log R_{23}$. However, only a few of the HII regions present values exceeding 0.85.

Fig. 10. Metallicity for NGC 5055.

Fig. 11. Correlation between $\log([OII]/H\beta)$ and the logarithm of excitation.

In Figure 10 we show the values of the metallicity versus the deprojected radius for NGC 5055. We can see that there is a very steep gradient in its inner parts, from $12+\log(O/H)=9.4$ to $12+\log(O/H)=8.5$. As van Zee et al. (1998) and Cedrés & Cepa (2002) have pointed out, this happens because the analytical form of the calibration does not explicitly take into account the turnover in R_{23} , so it can result in artificially high abundances for the inner HII regions.

For comparison, in Figure 11, we show the values of the metallicity versus the deprojected radius using a more modern calibration (Pilyugin 2007). Here, we can see that the results obtained using the calibration from Zaritsky et al. (1994) are larger than the metallicities obtained using this calibration and the gradient is smaller.

Fig. 12. Ionization hardness as a function of galactocentric radius for NGC 5055.

3.5. Ionization hardness

According to Christensen, Petersen, & Gammelgaard (1997), Bresolin, Kennicutt, & Garnett (1999), and Garnett (1989), the ionization hardness parameter, η , can be used to study trends in the temperature of the ionizing clusters, because there is a direct relation between η and the temperature.

To derive this parameter, we have to observe at least the [SIII] λ 9069 line. However, this emission line is rather weak and it falls on a region where the sensitivity of the CCD starts to drop. For this reason, observations of the [SIII] lines are available for only a few regions in NGC 5055.

In Figure 12 we plot the η parameter as a function of galactocentric radius for NGC 5055. Although our data in [SIII] have very large uncertainties, there is a clear relation between the two quantities, with η decreasing as a function of radius. Such gradients have been previously found by Vílchez & Pagel (1988); Zaritsky et al. (1994), and Cedrés & Cepa (2002) for other galaxies. This can be interpreted as a trend in the effective temperature of ionizing stars: the temperature is lower in the inner part of the galaxy and higher in the outer part, as was previously pointed out by Christensen et al. (1997), Bresolin et al. (1999) or Garnett (1989).

In Figure 13 we plot the logarithm of the ionization hardness parameter as a function of the logarithm of the abundance parameter R_{23} . Here, we also have a clear relation between both quantities, with a hardening of the radiation as $\log R_{23}$ decays, which implies an increase in metallicity.

Fig. 13. Relation between $\log \eta$ and $\log R_{23}$ for NGC 5055.

4. CONCLUSIONS

Using the catalogue of the HII regions of NGC 5055 compiled in Paper I, in conjunction with narrow-band images in the lines of $H\alpha$, $H\beta$, [OII], [OIII], [SII], and [SIII], we calculated several physical properties of the HII regions in this galaxy, which we can summarize as follows:

- We have measured the extinction for the HII region in the galaxy using the $H\alpha/H\beta$ ratio. The mean value for the extinction is of $A_V = 0.81$ mag.
- We also measured the $H\alpha$ equivalent widths for each HII region.
- We have measured the excitation for each HII region in NGC 5055. This quantity presents a clear gradient.
- Using a semiempirical calibration proposed by Zaritsky et al. (1994), we have derived the metallicity using strong oxygen lines. We find a clear gradient in the inner parts of the galaxy. We also show the values of the metallicity versus the deprojected radius using another calibration (Pilyugin 2007). With this calibration we can see that the results obtained using the calibration from Zaritsky et al. (1994) are larger, and that the gradient is smaller.
